## ABSTRACT

Activated carbon cloth (ACC) was tested to evaluate its ability to maintain physical adsorption properties over an extended series of adsorption/desorption cycles.

Adsorption consisted of saturation with a volatile organic compound (VOC). Benzene and acetone were selected as the test VOCs due to their commonality in indoor air and potential threat to human health. Desorption of these VOCs was achieved through direct electrical resistance heating (DERH) regeneration using an alternating current to increase bulk ACC temperature to 140°C. The heat generated was due to the resistive property of the ACC's fibers (resistivity of  $1-2 \cdot 10^{-2} \Omega \cdot \text{cm}$ ).

ACC-20 (specific surface area of 1610 m<sup>2</sup>/g and effective micropore volume of 0.636 cm<sup>3</sup>/g) was selected for this work due to its high adsorption capacity for benzene above concentrations of 200 ppmv.

The ACC-20 was tested by three similar methods. The first method involved DERH for two 6 hour periods with property evaluation after each period. The second method combined benzene saturation with DERH regeneration while the third combined acetone saturation with DERH regeneration. Both the second and the third methods were carried out for 50 adsorption/desorption cycles with property evaluation after every ten cycles.

Adsorption properties were measured by Brunauer, Emmett, and Teller (BET) nitrogen isotherms. The isotherm data were converted into specific surface area and effective micropore volume by use of the BET equation and the Dubinin Radushkevich

(DR) equation, Harkins Jura (HJ) equation, and single point method respectively. Changes in the adsorption properties of the ACC-20 were 2.2 % for BET specific surface area and 2.4 % for HJ effective micropore volume for the 12 hour DERH heated sample, 2.6 % for BET specific surface area and 3.1 % for HJ effective micropore volume for the 50 cycle benzene saturated sample, and 3.9 % for BET specific surface area and 3.8 % for single point effective micropore volume for the 50 cycle acetone saturated sample. All of these values were within the experimental error of 5.5% for BET specific surface area and 8.4 % for HJ effective micropore volume.

In addition, the purity of the VOCs was determined not degraded during the regeneration of ACC-20 by DERH.

A scaled-up estimate for an indoor air filtration system indicated that regeneration costs could be \$1450/yr for an air stream with a constant 100 ppbv benzene concentration and a flow of 57m<sup>3</sup>/min.

## 1 Introduction and Research Objectives

This research contributes to the development of a new technology for gas stream removal of volatile organic compounds (VOCs) by applying the principles of activated carbon adsorption coupled with cryogenic vapor recovery. Overall, activated carbon cloth (ACC) will be placed in a fixed bed arrangement with built in electrodes for direct electrical resistance heating (DERH) using alternating current across the ACC.

This work evaluates the effect of repetitive DERH on a single layer of activated carbon cloth attached to electrodes in a glass reactivation cell was studied. The concept of adsorption capacity regeneration by DERH first presented by Economy and Lin (1974) was extended here to evaluate the cloth's physical adsorption properties over a series of adsorption/desorption cycles. ACC was saturated with a VOC and then regenerated through DERH. The properties used to quantify the material's adsorption durability after a specific number of VOC saturation/DERH regeneration cycles were specific surface area and effective micropore volume. The power requirements to achieve complete regeneration of the sample activated carbon cloth were measured to aid in the determination of the cost effectiveness of DERH as opposed to regeneration through steam or heated gas. Furthermore, the desorbed vapor released during all regeneration was sampled to determine the purity of the VOC for recycling in an industrial process (e.g., spray paint booths, bulk fuel transfer, or part cleaning solvents).

This research is significant due to increased needs to remove indoor air contaminants, such as VOCs, because long exposure times are believed to have

serious negative health effects (Sterling, 1984 and Tancrede, 1987). Additionally, industries which emit VOCs to the atmosphere as a result of manufacturing processes will soon require new methods of control when the EPA promulgates the emission standards for the 189 hazardous air pollutants (HAPs), many of which are VOCs, listed in the Clean Air Act Amendment of 1990.

### **1.1 Manufacture of Activated Carbon Cloth**

ACC is a cloth woven from carbon fibers then carbonized and activated through controlled oxidation heat treatment. The carbon cloth used in this research is woven from cured phenolic-aldehyde fibers made by acid-catalyzed cross-linking of melt-spun novolac resin with formaldehyde. The curing process renders the fibers both infusible and insoluble. The cloth is then carbonized and activated through a one step process in a steam or carbon dioxide atmosphere at 800° - 900°C. Surface areas produced from activation of this cloth can approach 3000 m<sup>2</sup>/g (Hayes 1981). The phenolic ACC was developed and patented by the Carborundum Company in the early 1970s through the work of Economy et al. (Hayes 1981). The final ACC material was produced and donated to perform this research by American Kynol, Inc. a subsidiary of Nippon Kynol, Inc.

### **1.2 Physical and Chemical Properties of Activated Carbon Cloth**

A micropore is defined as having a pore width,  $w$ , less than 20 Å (Dubinin, 1960). This definition is accepted as convention by the International Union of Pure and

Applied Chemistry (Bansal, Donnet and Stockli, 1988). The pores formed during activation of the carbon cloth are hypothesized to be elongated and slit shaped with a half width between 5 and 14 Å (Economy and Lin, 1974), making these activated carbons almost entirely microporous. This is significantly different from granular activated carbon which is thought to have branched pores, with micropores mainly inside of a larger pore structure. The location of the micropores on the surface of the fibers allows for highly rapid adsorption and desorption (Hayes, 1981). This characteristic along with the structure of the woven cloth allow for *in situ* DERH at a moderate temperature of 140°C (Cal, 1993). The ACC selected for these tests was ACC-5092-20 (henceforth denoted as ACC-20). ACC-20 has a BET specific surface area of 1610 m<sup>2</sup>/g, as determined by nitrogen (N<sub>2</sub>) adsorption at 77°C, and an effective micropore volume of 0.636 cm<sup>3</sup>/g, determined using five different reference vapors at 25°C (Foster 1992).

The electrical properties of the ACC-20 is important for the use of DERH. A moderate electrical resistance is needed to make a good resistance heater. Materials with extremely high resistances like glass or rubber will not conduct a sufficient amount of electricity for heating to occur. Conductive materials (i.e., copper and aluminum) produce very little heat due to the low resistance to current flow. In general carbon fibers (non-activated) have high resistances and in some cases can be used in insulating composite materials. However, carbon fibers may also be treated to become conductors with a resistivity as low as copper. Fibers are intercalated with alkali metals like potassium and cesium, nitric acid, and halogens through high temperature heat

treatment in a  $N_2$  atmosphere to form highly oriented pyrolytic graphite (HOPG) within the fiber. From Table 1.1 the low resistances of pan and mesophase pitch fibers are observed after intercalation at heat treatment temperatures (HTT) (Donnet and Bansal, 1990).

Activation of carbon fibers results in a decrease in resistivity from that of cured novoloid fibers but still has a higher resistivity than the HTT fibers (Hayes, 1993). From Table 1.1 the resistivity of the fibers can be compared to typical conductors and insulators

### **1.3 Physical and Chemical Properties of Volatile Organic Compounds**

As defined by Lewis (1989) a VOC is an organic compound with a vapor pressure,  $P_o$ , greater than  $10^{-2}$  kPa. This is a practical definition since compounds with higher  $P_o$  values are typically found at concentrations above  $0.1 \mu\text{g}/\text{m}^3$ . This concentration allows for greater ease of detection than semivolatile organic compounds (SVOC) with  $10^{-2} \text{ kPa} > P_o > 10^{-8} \text{ kPa}$  and concentrations in the  $\text{ng}/\text{m}^3$  to  $\text{pg}/\text{m}^3$  range (Nriagu, 1992). Benzene and acetone were selected as test VOCs for this research in keeping with previous work done by Fuerman (1992), Foster (1992), Cal (1993), and Graf (1994). The properties of these two VOC's which are important to this research are listed in Table 1.2.

## 2 Adsorption Theory

The adsorption properties of porous activated carbon have been observed since 1777 (Greg and Sing, 1982). By early this century adsorption was relatively well defined. In 1916 Langmuir published his monolayer equilibrium adsorption model and stated that charcoals were understood to be truly porous. He furthermore postulated that charcoals had cross linkage between long chain carbon molecules consisting primarily of carbon atoms. The high carbon content is a result of the majority of hydrogen and oxygen being driven off of the lignin precursor during the carbonization and activation processes.

This section discusses several methods of characterizing porous materials (specifically microporous activated carbon) which have been developed from Langmuir's time to the present day. The methods are employed in this paper to characterize ACC-20 by adsorption characteristics, and include, the adsorption isotherm, the specific surface area, and the effective micropore volume.

### 2.1 The Adsorption and Desorption Isotherms

Adsorption and desorption isotherms are plots of the measured number of moles ( $n$ ), or volume or mass of a gas (adsorbate) adsorbed by one gram of solid material (adsorbent) as a function of the relative pressure of the adsorptive gas,  $P/P_0$ .  $P$  is the partial pressure and  $P_0$  is the saturation vapor pressure of the adsorbate. An adsorbent's pore size is defined by the shape of its adsorption isotherm. There are five types of isotherms as defined by the Brunauer, Deming, Deming, and Teller (BDDT)

(1940) classification. The ACC-20 used in this work was previously determined to be an almost entirely microporous solid material (Foster, 1992). For microporous solid materials the adsorption isotherm will have the characteristic shape of a Type I isotherm as found in Figure 2.1. Plotting  $n$  versus  $P/P_o$  produces an isotherm without the characteristic slightly sloping straight line at  $P/P_o$  between 0.25 and 0.95 then the material is not completely microporous.

## 2.2 The BET Surface Area Model

Building upon Langmuir's (1916) model for equilibrium monolayer adsorption Brunauer, Emmett, and Teller theory (BET, 1938) develops a model for multilayered adsorption. The Langmuir equation may be simplified from its original version to read:

$$\frac{v}{v_m} = \frac{BP}{1 + BP} \quad (2.1)$$

where  $v$  is the adsorption phase volume adsorbed per gram of adsorbent;  $v_m$  is the volume required to cover one gram with a monolayer of adsorbate;  $B$  is an empirical constant; and  $P$  is the partial pressure of the adsorptive. Expanding this equation through a summation of multiple layers the BET equilibrium equation is determined:

$$\frac{v}{v_m} = \frac{c(P/P_o)}{(1 - P/P_o) (1 - P/P_o + c(P/P_o))} \quad (2.2)$$

where  $c$  is typically taken to be

$$c = e^{(q_1 - q_L)/RT} \quad (2.3)$$

and  $q_1$  is the heat of adsorption of the first layer;  $q_L$  is the heat of liquefaction for the subsequent layers;  $R$  is the ideal gas constant; and  $T$  is the absolute temperature (Brunauer, Emmett, and Teller, 1938).

To determine specific surface area using the BET model equation 2.2 is linearized.

$$\frac{1}{v \left( \left( \frac{P}{P_o} \right) - 1 \right)} = \frac{1}{v_m c} + \frac{c-1}{v_m c} \left( \frac{P}{P_o} \right) \quad (2.4)$$

After measurement of  $v$  and  $P/P_o$  from 0.01 to 0.25 (Foster, 1992) a plot is constructed from equation (2.4) of  $1/[v(P/P_o - 1)]$  versus  $P/P_o$ . The slope,  $(c-1)/v_m c$ , and intercept,  $1/v_m c$ , are determined through a least squares curve fit (Greg and Sing, 1982). These values are then used to calculate  $v_m$  and  $c$ :

$$v_m = \frac{1}{\frac{c-1}{v_m c} + \frac{1}{v_m c}} \quad (2.5)$$

$$c = \frac{v_m}{\left[ \frac{1}{(v_m c)} \right]} \quad (2.6)$$

Now the surface area,  $A_{BET}$  is calculated using a control volume approach:

$$A_{BET} = \frac{a_m N_A v_m}{(22,414 \text{ cm}^3 (\text{STP})) (10^{20} \text{ \AA}^2/\text{m}^2)} \quad (2.7)$$

where  $a_m$  is the cross sectional area occupied by one molecule of adsorbate and  $N_A$  is Avagadros number. For nitrogen,  $a_m$  is taken to be  $16.2 \text{ \AA}^2$  (Greg and Sing, 1982).

## 2.3 Micropore Volume Equations

Quantification of effective micropore volume can be characterized with several different equations applied to the  $N_2$  adsorption isotherm data. Methods of estimating the micropore volume include the Dubinin Radushkevich (DR) equation (Dubinin, 1989), the Harkins and Jura (HJ) statistical thickness plot (Harkins and Jura, 1943, Lowell and Shields, 1984) and a single point volume adsorbed value.

### 2.3.1 The Dubinin Radushkevich (DR) Equation

The DR equation was developed with Dubinin's theory of the volume filling of micropores (TVFM) and is best applied as a model when using benzene or some other VOC as a reference vapor (adsorptive). Dubinin (1988) demonstrated that as a reference vapor,  $N_2$  at  $77^\circ \text{ K}$  is not equivalent to benzene at  $293^\circ \text{ K}$ . Further, benzene was shown to be more appropriate for characterization of a material's adsorption properties and microporous structure. With this caveat in mind the DR equation is used only to calculate the effective micropore volume from the measured values for the volume adsorbed and the relative pressure of  $N_2$  and is not used to model the ACC-20 adsorption characteristics for VOCs.

The DR equation is

$$W = W_o \exp \left[ - \left( \frac{A}{\beta E_o} \right)^2 \right] \quad (2.8)$$

where  $W$  is the volume of the adsorbate adsorbed by one gram of the carbon;  $W_o$  is the total micropore volume available to the adsorbate;  $A$  is the differential molar work or the negative of the Gibbs free energy;  $\beta$  is the similarity coefficient, or the affinity factor, of the standard vapor to the reference vapor (benzene); and  $E_o$  is the characteristic adsorption energy. For  $N_2$ ,  $\beta = 0.34$  (Bansal et al., 1988). The differential molar work,  $A$ , calculated as:

$$A = -\Delta G = RT \ln (P_o/P) \quad (2.9)$$

$E_o$  is inversely related to the slit-pore half width,  $x_o$ :

$$k = x_o E_o \quad (2.10)$$

such that a constant structural factor,  $k$ , of 12.0 kJnm/mol is assumed to determine  $x_o$  (Dubinin, 1989).

The linearized DR Equation:

$$\ln (W) = \ln (W_o) - \left( \frac{1}{\beta E_o} \right)^2 A^2 \quad (2.11)$$

is used to plot  $\ln(W)$  against  $A^2$  for a range of  $P/P_o$  of 0.001 to 0.500 where  $W_o$  and  $x_o$  are determined from the slope and intercept respectively.

### 2.3.2 The Harkins Jura (HJ) statistical thickness plot

The concept of plotting the statistical thickness was originally proposed by Lippens and de Boer (1965) as a method of testing superposability of isotherms to standard isotherms (Lowell and Shields, 1984). Based on the so-called t-curve, a plot of the standard isotherm is produced where the statistical thickness,  $t$ , of the adsorbed film, rather than  $P/P_o$ , is the independent variable and the dependent variable is the volume adsorbed  $V_a$ . The thickness is related to the number of molecular layers,  $n_a/n_m$  (or  $V_a/V_m$ ) expressed as:

$$\frac{n_a}{n_m} = \frac{V_a}{V_m} = \frac{t}{\sigma} \quad (2.12)$$

where  $t$  is the average total thickness of all layers adsorbed and  $\sigma$  is the thickness of one layer ( $\sigma = 3.54 \text{ \AA}$  for  $N_2$  at  $77^\circ \text{ K}$ , assuming hexagonal close packing).

The empirical HJ equation is given as:

$$\log (P_o/P) = B + \frac{A}{V_a^2} \quad (2.13)$$

where  $A$  and  $B$  are empirical constants with  $A$  related to the thickness and the volume of a monolayer and  $V_a$  is the volume adsorbed (Harkins and Jura, 1944). This model is modified to calculate a thickness:

$$t = \left[ \frac{13.99}{(0.034) - \log (P_o/P)} \right]^{1/2} \quad (2.14)$$

where 13.99 and 0.034 are empirical constants (De Boer et al., 1965). By plotting  $V_a$  against  $t$  for  $P/P_o = 0.001$  to 0.7 and performing a least squares linear curve fit to the values that fit a line on the level part of the isotherm. The values selected here to best fit the Type I isotherm were for  $t$  from 0.45 to 0.70. The external surface area and micropore volume are then determined from the slope and intercept of the fitted line respectively (Micromeritics, 1987).

### **3 Experimental Equipment and Procedures**

#### **3.1 Experimental Equipment for Saturation and Regeneration**

The intent of this experimental study is to determine the effects of repetitive heating of ACC by the application of an alternating current across the cloth to remove benzene and acetone. The effect of DERH is to be defined as any change in the adsorption properties of the cloth through changes in the micropore surface area and volume.

The experimental apparatus, Figure 3.1, centers around a glass test cell that is 40 cm long and 1.7 liters in volume with two opposing aluminum electrodes that act to support the cloth sample as well as provide electrical connections. A variable AC voltage transformer (variac), model W10MT3, provides a potential difference across the sample and current is monitored by a Fluke 77 multimeter. The bulk temperature of the cloth is monitored by a type K thermocouple detected by a digital multimeter (Omega 881C). Laboratory grade N<sub>2</sub> (99.95 % pure) is used to purge air and contaminants from the test cell. The exhaust gases are vented to the atmosphere via 280 lpm (10 cfm) lab venthood.

#### **3.2 Experimental Procedure**

##### **3.2.1 Method of Saturation and Electrical Regeneration**

ACCs are saturated with VOC and then regenerated through direct electrical resistance heating to complete one saturation/regeneration cycle. To determine the

durability of the cloth's adsorption properties it is necessary to run an extended number of test cycles. This section provides a detailed explanation of how this process is conducted.

ACC samples are first analyzed on a Micromeritics™ ASAP 2400 surface area analyzer, as described in section 3.2.2, to determine baseline surface areas and pore volumes prior to saturation or regeneration treatment. Prior to and between experiments ACC samples are stored in airtight bottles purged with N<sub>2</sub> to minimize adsorption of water vapor or contaminants.

An ACC sample is loaded into the test cell by attaching it to the electrodes and reassembling the cell. An evaporation dish containing liquid VOC (benzene or acetone) is placed into the test cell downstream of the sample. During placement the evaporation dish the cell is purged with N<sub>2</sub> at a minimum gas flow rate of 3 lpm. After reassembly purging is continued for a total time of 3.5 minutes. The time and flow rate for purging are estimated to provide 99.93 percent removal of air from the cell assuming that complete mixing occurs in its 1.7 liter volume. The nitrogen flow is then shutoff, the exhaust port capped and the sample is allowed to adsorb the VOC for twenty minutes at which point it is estimated that saturation is reached at room temperature (21°C). The sample is now considered saturated with VOC and the cell is prepared for DERH regeneration. Prior to DERH the evaporation dish containing the liquid VOC is removed from the test cell while purging the cell with nitrogen to prevent air from entering the test cell. During this purging it is likely that some of the VOC will desorb from the cloth as the vapor pressure in the cell is decreased by nitrogen

ventilation.

The cell is reassembled and purging continues for a total time of 3.5 minutes, then the electrical leads are attached to the electrodes with the Fluke 77 multimeter in series with the sample to measure current.  $N_2$  flow is set at 0.5 lpm and the sample is regenerated by electrical heating at a bulk sample temperature of  $140^{\circ}\text{C} \pm 10^{\circ}\text{C}$  for 20 minutes. This will require a voltage between 8 and 12 volts and a current between 0.7 and 1.1 amperes for a typical sample of 100 to 150 mg.

This procedure is repeated for ten cycles and then the ACC sample is analyzed on the ASAP 2400 to obtain measurements the specific surface area and the effective micropore volume. The samples are analyzed at 0, 10, 20, 30, and 50 cycles to measure for changes to the physical adsorption properties of the fibers in the cloth.

### **3.2.2 Method of ACC Physical Characterization**

The Micromeritics™ ASAP 2400 surface area analyzer is a automated, multiport,  $N_2$  BET isotherm measurement instrument. It has 12 degas stations and 6 analysis stations to allow for a high sample throughput. Analysis is controlled by an IBM AT computer with the ASAP 2400 version 3.01 software. The  $N_2$  data measured are volume adsorbed or desorbed, partial pressure and saturation pressure. From the data the software can generate plots and calculate values for isotherms, surface area, total pore volume, and micropore surface area and volume. The calculations use the analysis methods of Langmuir (1916), BET (Brunauer, Emmett, and Teller, 1938), HJ (Harkins and Jura, 1943) and others.

To test an ACC sample it is loaded into a clean dry analysis tube (Prior to loading the sample the tube is weighed on a Mettler AE260 analytical balance with a sensitivity of 0.1 mg, to determine its mass). With the sample placed inside, the tube is loaded onto one of the degas stations. Degassing is carried out at 50 torrs absolute pressure and 140°C until desorption of gases from the sample is no longer detectable. The degas process takes between 12 and 48 hours depending on the compound adsorbed.

When the ACC has completed degassing the sample will be able to maintain a vacuum below 30 torrs with less than a 5 torrs change over a 2 minute test period. In unloading the tube is charged with N<sub>2</sub> before it is removed from the degas station. After cooling to room temperature the sample is reweighed on the analytical balance and the difference in mass from the tube is taken to be the ACC sample mass. Now the sample is ready for N<sub>2</sub> adsorption/desorption analysis.

The ASAP 2400 measures N<sub>2</sub> adsorption/desorption at 77.25°K (boiling point of nitrogen), this requires the dewar below the analysis station to be filled with liquid N<sub>2</sub>. The sample tube is loaded onto the analysis port and the sample run conditions are programmed into the computer with the sample mass. After analysis the data and calculated values may be stored on electronic media for later retrieval.

### **3.2.3 Measurement of VOC Vapor Purity during Regeneration**

To recycle a VOC desorbed from a fixed bed it is necessary to maintain VOC purity in the capture process. In this part of the experiment it is determined if the VOC, here benzene or acetone, is contaminated or altered by electrical regeneration. Equipment

used includes the glass test cell apparatus, a Hewett-Packard gas chromatograph (GC) series HP5890, and a gas tight syringe.

Prior to testing the sample mass required to adsorb a quantity of benzene that would be detectable by the GC is calculated. By assuming that benzene behaves as an ideal gas, the ideal gas law,  $PV_{\text{gas}} = nRT$ , is used with  $\rho = m/V_{\text{ads}}$  to write a relationship between the adsorbed volume,  $V_{\text{ads}}$  and the volume the adsorbent would occupy as a gas,  $V_{\text{gas}}$ , at some temperature, is written as:

$$\frac{V_{\text{ads}}}{V_{\text{gas}}} = \frac{PMW}{\rho RT} \quad (3.1)$$

where  $P$  is the partial pressure of the gas,  $MW$  is the molecular weight, and  $\rho$  is the density of the adsorbed benzene. The GC has a minimum detection limit of 50 ppmv so a minimum desired concentration level is arbitrarily selected at 200 ppmv. The micropore volume for the ACC-20 is 0.653 cc/g when using benzene (Foster 1992). From equation 3.1 and these two values the minimum required sample size is calculated to be 2.2 mg. Since the typical sample size used for the saturation/regeneration experiment is larger than 100 mg the GC will have no difficulty in detecting and testing benzene purity.

The sample is saturated and regenerated in the same method as described in section 3.2.1. One exception to this is no  $N_2$  flow during regeneration. After reassembling and purging the test cell the  $N_2$  flow is shutoff and the exhaust port is capped. Prior to regeneration a sample of the test cell gas is drawn with a gas tight syringe. Analysis of the gas sample with the GC determines initial VOC concentration.

During regeneration the test cell gas is sampled at two minute intervals and analyze to determine VOC concentration and composition.

### **3.3 Quality Control Procedures**

The rotameter used to determine the purge nitrogen gas flow rate was calibrated by using a 1000 ml bubble meter. The calibration curve produced by the bubble meter is linear by least squares curve fit (Figure 3.2). This linear relationship is used to convert the rotameter values into liters per minute (lpm) of gas flow.

The variac voltage was calibrated by using a separate sample in the test cell and the Fluke 77 multimeter in parallel with the sample circuit. Test voltages on the variac ranged between 0 and 15 volts. This range provided sufficient heating for a typical sample of 100 to 150 mg. The calibration curve for the W10MT3 variac, General Radio Co. is shown in Figure 3.3 is utilized to adjust the voltage given by the variac to the actual voltage. The 3PN1010 variac was used on a few of the acetone regeneration cycles, the calibration curve for this variac is given in Figure 3.4.

## 4 Experimental Results and Discussion

This section provides the experimentally determined values which characterize the ACC-20 as it is exposed to numerous adsorption/desorption cycles through VOC saturation followed by DERH. Those values include the BET specific surface area, DR, HJ and single point effective micropore volumes. All values are calculated from the BET adsorption isotherm with  $N_2$  as the standard vapor. Error experienced in analyzing was determined by repetitive testing of a single sample without cyclical treatment or DERH.

### 4.1 Experimental Results

The ASAP 2400 recorded  $N_2$  adsorbed and desorbed at relative pressure from 0.001 to 1.0 to produce the adsorption and desorption isotherms. Three ACC-20 samples were analyzed on the ASAP 2400. Each sample was initially analyzed to establish baseline values for the specific surface area and effective micropore volumes. The first sample did not undergo VOC saturation. The ACC-20 was heated by DERH for two six hour periods with analysis after each period. The second sample of ACC-20 was cycled by saturation with benzene and regeneration by DERH. The third sample of ACC-20 was cycled by saturation with acetone and regeneration by DERH. Both the second and third samples were subjected to 50 adsorption/desorption cycles with analysis after every 10 cycles.

The  $N_2$  adsorption and desorption isotherms in Figures 4.1 to 4.3 are standard Type I isotherms and clearly define this ACC-20 as microporous (Greg and Sing,

1985). The variation between the isotherms produced before treatment and those produced after exposure to an alternating current (AC) is less than 7 %. The AC power is supplied at 1.67 amps and 11 volts to heat the sample at 140°C for periods of 6 hours . Figure 4.2 and Figure 4.3 for benzene and acetone cycled ACC-20 respectively indicate similar results to the electrically heated ACC-20. Each figure shows the adsorption and desorption isotherms for the baseline and after samples were exposed to 50 saturation/regeneration cycles. A slight increase in the volume adsorbed at 12 hours and 50 cycles may be noted in these figures. However, the increase is small and below a measurable significance.

The DR effective micropore volume was determined by a plot of the natural logarithm of  $N_2$  volume adsorbed,  $\ln(W)$ , against the square of the differential molar work,  $A^2$ , calculated from the measured relative pressure of  $N_2$ . As seen in Figure 4.4, the isotherm data for the 20 cycle acetone treatment is graphed on a DR plot. A least squares linear curve fit provides a value of -0.0220 for  $\ln(W_0)$ , which results in a  $W_0$  of 389.9  $cm^3/g$  for the adsorption capacity of  $N_2$  gas or an effective micropore volume of 0.6031  $cm^3/g$ .

As an alternative method of calculating the micropore volume a HJ statistical thickness plot (t-plot) is generated. Figure 4.5 provides a t-plot of 20 cycle acetone saturation/DERH regeneration and indicates the volume of  $N_2$  gas adsorbed is 366.15  $cm^3/g$  or a effective micropore volume 0.566  $cm^3/g$ . Also, the single point effective micropore volume is measured at a  $P/P_0$  of 0.95. For a completely microporous material like the ACC the values measured are close to those calculated with the DR

and HJ equations. Tables A.1 to A.13 provide the data measured and results calculated in determining the micropore volumes for each 6 hour heat treatment or 10 cycle sample.

When the ACC-20 is heated to 140°C for extended times using DERH the material does not show any appreciable change in specific surface area or effective micropore volume. Table 4.1 compares these properties after 0, 6, & 12 hours of heating time. The percent difference ( $\Delta$  %) is taken as the change from the properties found at the 0 hour as a baseline. The ACC-20 sample is shown to have increased in BET specific surface area by only 2.2 % while the largest effective micropore volume increase is seen by the HJ equation at 2.4 %.

Table 4.2 gives calculated adsorption values for the 0 to 50 cycles of benzene saturation with DERH regeneration. A 40 cycle analysis was not performed due to the lack of significant change between 0 and 30 cycles. Samples were not cycled beyond 50 cycles due to the manual effort and time required in each saturation/regeneration cycle and a three day per sample BET analysis period.

The combination of benzene saturation with DERH regeneration is shown not to significantly effect the adsorption capacity of the ACC-20 as determined by its affinity for N<sub>2</sub> adsorption at 77.25°K. The largest changes are an increase in the BET specific surface area by 7.7 % and the HJ effective micropore volume by 8.49 %, which occur after 20 cycles. This variation is considered small when compared to error values of more than 10 % reported by Dubinin (1989) and Cal (1993). Likewise the cycles of acetone saturation with DERH regeneration have similar results with surface area

increasing by 3.9 % and single point effective micropore volume increasing by 3.8 % as listed in Table 4.3.

## **4.2 Estimation of Error in Isotherm Measurements**

To determine the accuracy provided by the ASAP 2400 when measuring the microporous ACC-20 samples, a clean unused ACC sample was tested three times sequentially to check for the repeatability of measured results. An average value and standard deviation were calculated along with each runs variation from the initial value and is provided in Figure 4.4. This sample was found to have the highest variation with an 8.4 % increase of the HJ effective micropore volume in the third test.

## **4.3 VOC Purity and Contamination Produced during Electrical Regeneration**

The 123.5 mg ACC-20 sample used for the benzene cycle test was regenerated and then saturated with benzene. In the next regeneration gas samples (10 cm<sup>3</sup> each) were drawn out of the test cell and injected into the GC as outlined in section 3.2.3. A single peak for benzene was produced with a concentration near 5% by volume and no impurities were found. A similar experiment on the 131 mg ACC-20 acetone sample produce a single peak for acetone with no impurities found.

## **4.4 Electrical Resistance and Power Requirement**

The electrical current and voltage were measured over a temperature range of 23° to 300°C for a 4.5 cm x 4.5 cm square sample of ACC-20 oriented with the cloths

primary weave in the direction of current flow. Figure 4.6 shows the relation between current and temperature which was determined to be linear over this temperature range. Using ohms law the resistance of the ACC-20, plotted as a function of temperature in figure 4.7, was found to have an asymptotic decline from 50° to 270°C. However, it is not understood why the resistance briefly increases before reaching 50°C. This decrease in resistance of the bulk cloth over increasing temperatures is similar to the decrease in resistivity found on pristine PAN and pitch fibers by Lee, et al. (Donnet and Bansal, 1990).

The power required to achieve heating of the cloth was calculated from the measured values of the root mean square voltage,  $V_{RMS}$ , and current,  $I_{RMS}$ , with the assumption that the phase angle,  $\theta$ , between the voltage and the current was 0° (Power =  $V_{RMS} I_{RMS} \cos \theta$ ). Thereby a worst case estimation of power consumed is provided. The power requirements in Figure 4.8 indicate a linear relationship to temperature when a single sheet of ACC-20 is heated by DERH..

#### **4.5 Economical Estimation of DERH Regeneration**

Using the power requirements calculated for the 4.5 cm X 4.5 cm square sample of ACC-20, Graf's (1994) filter mass requirements of 1.36 Kg for ACC-10 in a full-scale filtration estimate for 57 m<sup>3</sup>/min (2,000 cfm) indoor air ventilation and a 2/1 relationship of low concentration adsorption capacities between ACC-10 and ACC-20 (Foster, 1992) an estimation of energy costs is made for a full-scale filtration system. The energy required per regeneration is calculated from a constant power requirement of 35

W over an estimated 30 minutes for a 400 mg sample. By assuming an energy price of \$0.08/kWhr and a regeneration interval of 2.4 days the energy cost would be \$1450/year. This cost seems to be slightly high considering that a ventilation rate of 57 m<sup>3</sup>/min (2,000 cfm) will only provide ten air changes per hour to a 223 m<sup>2</sup> (2,400 ft<sup>2</sup>) building

It is important to notice that this is strictly the cost to heat the filter and does not include the cost for preheating N<sub>2</sub>, or energy to run additional fans and damper motors. This cost could vary significantly for a fixed bed when taking into account the possibility of increased conductance due to bed configuration, nonlinear power/temperature relationships or the cooling effect of a N<sub>2</sub> flow through the ACC. Further, the power requirement was based on heating the ACC-20 while suspended in a glass test cell surrounded by 1.7 liters of N<sub>2</sub> gas. Therefore, it is anticipated that convection heat transfer in the cell was significant and that the power requirements to produce the same temperatures in a fixed bed with preheated nitrogen flow could be substantially lower.

## **5 Conclusions and Recommendations**

### **5.1 Conclusions**

The activated carbon cloth (ACC-20) displays a high level of durability by maintaining adsorption characteristics at relatively constant values for up to 50 adsorption/desorption cycles, with VOC adsorbate saturation and direct electrical resistance heating (DERH) regeneration at a temperature of  $140 \pm 10^{\circ}\text{C}$ . The BET specific surface area and effective micropore volume remain within 8 % of the baseline values measured before cyclic testing. The DERH current and power requirements for suspended sheet ACC-20 have increasing linear relationships with the desorption temperature, while the bulk sample resistance decreases with increasing desorption temperatures above  $60^{\circ}\text{C}$ . Scaled up estimations of power requirements and energy costs indicate that DERH could be costly for removal of low concentration VOCs in an indoor air environment when the VOC concentration is a constant 100 ppbv of benzene, regeneration is required every 2.4 days, and there are 10 air changes per hour. The benzene and acetone adsorbed by the ACC-20 were tested for purity during regeneration by DERH. It was determined that these two VOCs do not breakdown and are not contaminated by the carbon cloth.

### **5.2 Recommendations**

Quantifying the ACC-20 adsorption characteristics by measurement of the effective micropore volume would be more appropriately determined by using the actual test

VOC or an approved reference vapor (benzene) in a total gas analyzer or a gravimetric balance apparatus (Cal, 1993). This will allow the Dubinin-Radushkevich equation to be applied as a model to various VOCs using affinity coefficients,  $\beta$ . Additionally this would be a better determination of the ACC's ability to regain an original adsorption capacity for the particular contaminant.

Kinetic studies of regeneration times and power requirements should be performed on a pilot scale fixed bed adsorption system to accurately determine the feasibility and economics of applying DERH as the method of *in situ* regeneration as opposed to regeneration by heated gas or steam.

Stability and purity measurements for other VOCs (acetaldehyde, methylethyl ketone, toluene, etc.), found in indoor and industrial air streams, need to be made to determine wide spread application of this regeneration method.
